

Some More Examples

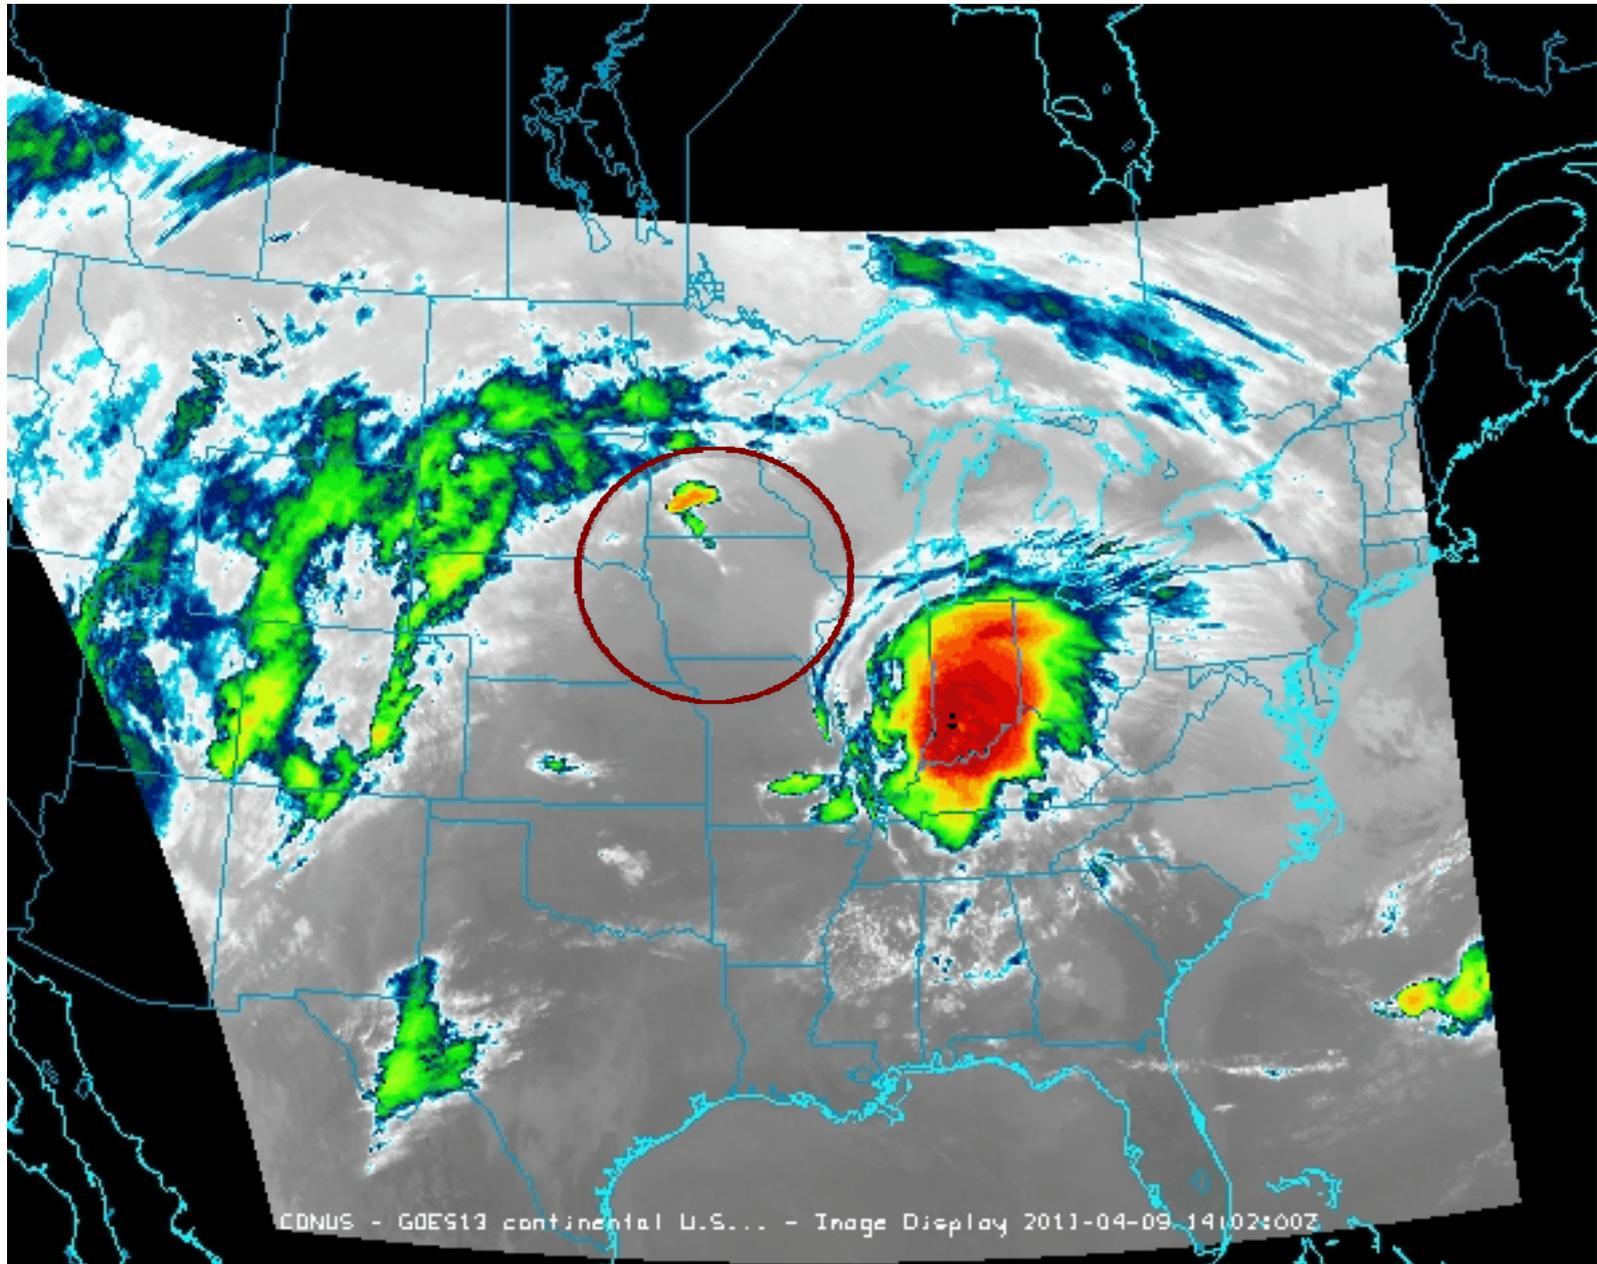

April 9, 2011 – Mapleton, IA (western Iowa)

- Tornado struck Mapleton around 00z,
- Convection starts in far eastern Nebraska about 2230z just as area became substantially more unstable
- Note that Upper-Level dry air moves over same area precisely at time of convection initiation
 - Especially obvious with 17z and 20z runs
- Also note the activity through North and South Carolina with very large hail.
 - This is associated with a push of high Lower-Level Theta-E and instability into a previously stable area.

June 08, 2011- Southern Wisconsin

- Convection begins about 00Z
 - Confined to a SW to NE oriented strip of moisture moving NE through southern Wisconsin
- Upper-Level dry air pushes east over this band of moisture setting off convection.
- By 02Z, the satellite loop show the deepest convection (darkest reds) moving SE within the large cloud shield, in the direction of the Upper-Level dry boundary.
- Precipitable Water loops useful here as well as θ_e
- SPC reports document large hail and strong winds with these storms and several tornadoes

Theta-E Deep-Layer Difference (Mid-Low) (K)

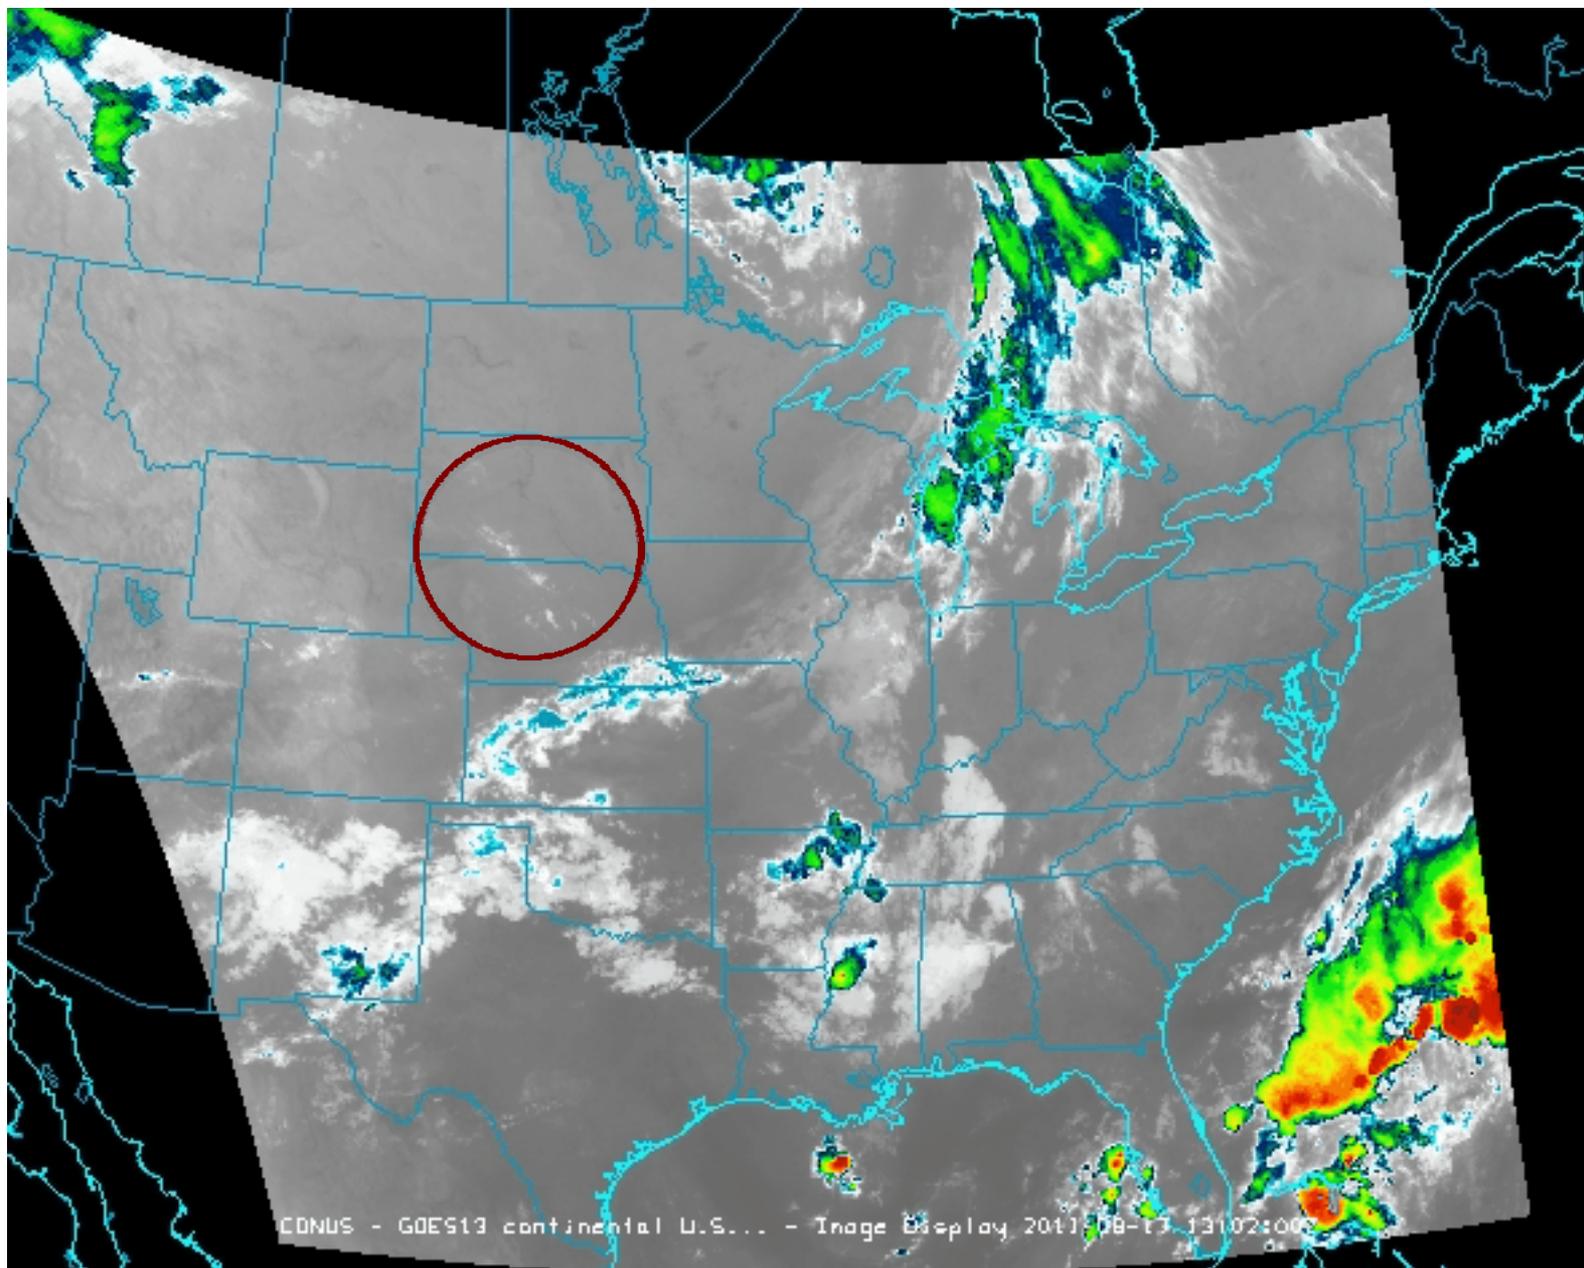

August 17, 2011 – Central So. Dakota / north-cent. Nebraska

- Convection begins after 22z along leading edge of Upper-level dry air as it moves over N-S oriented strip of moisture which itself is moving north.
- Once this leading edge passes through the moisture, the storms quickly die as they have lost their moisture source.
- NearCasts indicated that these storms would dissipate just as quickly as they developed.
- Precipitable Water data show the dry air moving over the strip of moisture from the west, then exiting to the east.
- SPC documents that at least 2 of these storms produced severe weather

Feb 28-29, 2012 – Branson, MO (south central MO)

- Tornado struck Branson about 07Z on the 29th
 - *In the middle of night when most people were asleep*
 - *Early warning would have reduced injuries*
- NearCasts showed a maximum in Convective Instability moving through southern MO - precisely along the path of some of the deepest convection.
- Upper-level θ_e loop shows the dry air moving over the strip of moist LL air
- SPC reported many severe storms along the path of this edge of instability.

NearCasting Recap

- Nearcasts successfully provide short-range forecasts of timing and locations of severe thunderstorms, especially for hard-to-forecast, isolated summer-time convection when NWP systems have least skill

NearCast 1-9 hour forecasts allow forecasters to quickly monitor where hazardous weather will (or will not) form.

NearCasts are:

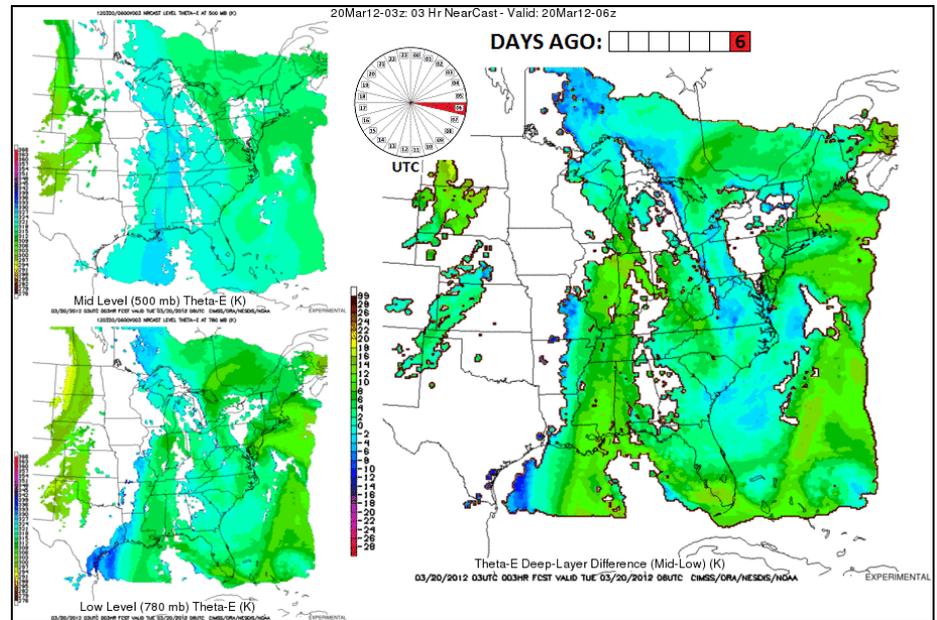

- Useful in improving subjective forecasting*
- Available within minutes of observation times,*
- Are frequently updated (hourly or sub-hourly), and*
- Rely on quality GOES sounder observations that are not included over land in traditional NWP systems*
- Valuable tools for forecasters to validate and enhances upon NPW and ensemble products*
 - - Show the potential of GOES-R*

What Next?

NearCast Model has been modified to run anywhere on the globe

- *Uses NCEP GFS data for Heights and initial Winds*
- *Output as web pages or GRIB-II*

Exposing Forecasts to satellite NearCasts

6 day loop of previous 6-hr NearCasts

Recommend test and evaluate over Europe/Africa using SEVIRI sounding

- *Options to get SEVIRI data from Eumetsat or CIMSS*
 - *Eumetsat is preferable since we would test operational products*
- *Need to define areas to perform evaluations*
- *Need volunteers for testing (Poland has expressed interest already)*
